Abstract

Whether navigating a building, operating a robot, or playing a game, an agent that acts effectively in an environment must first learn an internal model of how that environment works. Partially-observable Markov decision processes (POMDPs) provide a flexible modeling class for such internal world models, but learning them from observation-action trajectories alone is challenging and typically requires extensive environment interaction. We ask whether language-model priors can reduce costly interaction by leveraging prior knowledge, and introduce *Pinductor* (POMDP-inductor): an LLM proposes candidate POMDP models from a few observation-action trajectories and iteratively refines them to optimize a belief-based likelihood score. Despite using strictly less information, *Pinductor* matches the performance and sample efficiency of LLM-based POMDP learning methods that assume privileged access to the hidden state, while significantly surpassing the sample efficiency of tabular POMDP baselines. Further results show that performance scales with LLM capability and degrades gracefully as semantic information about the environment is withheld. Together, these results position language-model priors as a practical tool for sample-efficient world-model learning under partial observability, and a step toward generalist agents in real-world environments. Code is available at <https://github.com/atomresearch/pinductor>.

1 Introduction

Consider an agent dropped into an unfamiliar building, deployed on a new robot, or placed in an unseen game. Before it can act competently, it must construct an internal model of how the world responds to its actions: what the hidden state is, how the environment evolves, what it can expect to observe, and what rewards its actions yield. Building such a model from first-person experience, rather than from a handwritten specification, is a long-standing problem in reinforcement learning and embodied AI [1–3].

When the world is not fully observable, a natural formalism is the partially observable Markov decision process (POMDP), which represents uncertainty over states, transitions, observations, and rewards [4, 5]. POMDPs provide a flexible modeling class for internal world models under partial observability, but learning them is practically demanding: classical approaches, including tabular estimators, predictive-state representations, and deep recurrent latent models, typically require large numbers of environment interactions, strong structural assumptions, or both [3, 6, 7]. Directly specifying POMDPs by hand, meanwhile, requires careful engineering and precise knowledge of the available solvers [8].

Figure 1: ***Pinductor* architecture overview.** Given a small set of offline observation-action trajectories and an environment description, an LLM proposes a POMDP world model in code (dashed arrows). The resulting model is used for filtering and planning during environment interaction, and is periodically refined by the LLM to optimize a belief-based likelihood objective (solid arrows).

A recent line of work asks whether large language models (LLMs) can substitute for some of this interaction by providing strong priors over world dynamics. Rather than using the LLM itself as a simulator, which can be slow, expensive, and prone to inconsistency [9, 10], these methods use the LLM to write an executable world model in code and then refine that code against observed trajectories [10–13]. Code-structured world models inherit the LLM’s prior knowledge of common environments while remaining precise, auditable, and cheap to query at planning time.

Almost all of this work, however, makes a critical simplifying assumption: that the latent state is available for learning. WorldCoder [11], GIF-MCTS [10], and most program-synthesis methods assume fully observable environments. The closest precursor to our work, POMDP Coder [14], extends LLM-guided program induction to POMDPs, but still relies on post-hoc full observability: after each episode, the agent is given access to the intermediate ground-truth states that it could not observe at decision time. In many settings, such as robots operating in cluttered or human-occupied spaces, or agents playing imperfect-information games, neither online nor post-hoc state access is available. Methods that require this privileged signal, therefore, cannot be applied. Whether LLM priors are powerful enough to compensate for the loss of ground-truth state supervision is the open question we address in this work.

To address this question, we introduce *Pinductor* (POMDP-inductor), a method that induces executable POMDP world models from observation–action–reward trajectories alone. *Pinductor* uses an LLM to propose candidate programs for the transition, observation, reward, and initial-state distributions, and then iteratively refines them using a belief-based likelihood score. Observation predictions are converted into soft likelihoods through a distance kernel, and candidate models are scored under their likelihood expected under the beliefs induced by their own filtering dynamics. Because this objective is computed from observations and self-induced beliefs rather than from privileged states, *Pinductor* applies in the strict POMDP setting where post-hoc state supervision is unavailable. A visual overview of the method is provided in Fig. 1.

We evaluate *Pinductor* on MiniGrid environments of varying complexity [15]. Despite using strictly less information than recent LLM-based methods, *Pinductor* matches their sample efficiency and performance, while largely outperforming standard tabular POMDP baselines, which struggle to learn from few trajectories. Additional experiments show that performance scales with LLM capability and degrades when explicit semantic information about the environment is withheld, indicating that the method relies heavily on the LLM and availability of textual information. Together, these results suggest that language-model priors can enable sample-efficient world-model learning without privileged state access, broadening the reach of existing methods to the partially observable settings that characterize many real-world deployments.

We summarize the paper’s contributions as follows:

1. **Observation-only POMDP induction.** We show that LLM priors are sufficient to induce executable POMDP world models from observation–action–reward trajectories alone, without access to ground-truth latent states at training or inference time.
2. **Belief-based model scoring.** We introduce a kernel-based likelihood objective that scores candidate POMDP programs under their filtered belief distributions, providing a per-step repair signal computable from observation–action–reward trajectories alone.
3. **End-to-end validation.** Across five partially observable MiniGrid tasks, we show that *Pinductor* matches the reward and sample efficiency of a privileged-state LLM baseline, outperforms non-LLM baselines, and induces belief states that become increasingly concentrated on the true latent state during planning.

2 Related work

LLM-guided POMDP and model induction The closest work to ours is POMDP Coder [14], which uses an LLM to propose and repair executable POMDP components using a coverage objective. However, it assumes privileged access to hidden states during training, both in demonstrations and through post-hoc full observability during online interaction. Other LLM-based approaches instead rely on extensive natural-language task descriptions to construct POMDP models [16], or use LLMs directly as planners rather than as model learners [17]. In contrast, *Pinductor* induces executable POMDP models from observation–action–reward trajectories and a minimal environment API, without access to hidden states.

LLMs for code-based world models Our approach fits within the broader paradigm of verbalized machine learning [18], where models are represented in the LLM’s token space, for example as executable code, and refined through language-based feedback. Prior work has used LLMs to generate code for reinforcement learning [19], fully observable world models [11, 20, 21], and algorithms more generally [22]. *Pinductor* differs by learning latent state generative models from trajectories in which the underlying state is never observed.

Learning in POMDPs A large body of work studies learning and planning under partial observability, including Bayes-adaptive methods [23, 24], spectral and variational approaches [25, 26], active-learning methods [27], and neural latent world models [28]. These methods can be effective, but typically require substantial data, specified model classes, tractable inference, or strong structural assumptions. *Pinductor* is complementary: given a compact latent state space and code interface, it uses LLM priors to search for explicit, auditable POMDP programs from few trajectories.

Theory-based reinforcement learning Theory-based RL uses programmatic, intuitive theories to support sample-efficient planning [29, 30]. These methods demonstrate the value of structured executable world models, but to date search within hand-designed hypothesis spaces whose primitives are tailored to the benchmark environments. *Pinductor* instead searches over executable POMDP components using an LLM prior, allowing it to induce models from sparse partially observed experience without a domain-specific theory language.

3 Background on POMDPs

A partially observable Markov decision process (POMDP) models sequential decision-making when the agent cannot directly observe the underlying state. In our setting, a POMDP is a tuple

$$(\mathcal{S}, \mathcal{A}, \mathcal{O}, T, O, R, \rho_0, \gamma) \quad (1)$$

where $\mathcal{S}$, $\mathcal{A}$, and $\mathcal{O}$ are finite sets of states, actions, and observations, respectively, cf. [1]. The transition model $T(s, a, s') = P(s' \mid s, a)$ gives the probability of moving to state s' after taking action a in state s , while the observation model $O(s', a, o) = P(o \mid s', a)$ gives the probability of observing o after taking action a and arriving in s' . The reward function $R(s, a, s')$ specifies the immediate reward received for transitioning from s to s' via action a . The initial state distribution $\rho_0(s) = P(s_0 = s)$ defines the probability of starting in state $s \in \mathcal{S}$, and the discount factor $\gamma \in [0, 1)$ determines the present value of future rewards.

Because observations are generally non-Markovian, an agent cannot condition only on its current observation to predict the future or choose an optimal action. Instead, it maintains a *belief state* Q , an approximate posterior probability distribution over latent states. Given an action a and a new observation o , the belief is updated by Bayes' rule:

$$Q'(s') \propto O(s', a, o) \sum_{s \in \mathcal{S}} T(s, a, s') Q(s). \quad (2)$$

This filtering update assumes access to an initial state distribution with which to initialize the belief, as well as a transition model and an observation model. In our setting, these models are not given and must be learned from experience.

For decision-making, the agent must also estimate a reward model. Given learned POMDP components, planning can then be performed in belief space using standard offline methods such as value iteration, online Monte Carlo tree search methods such as POMCP, or deterministic approximations such as DA*. In this paper, we focus on learning the model components: inducing the transition, observation, reward, and initial-state distributions required for belief filtering and planning from partially observed trajectories.

4 Methodology

Pinductor learns executable POMDP models from trajectories containing actions, observations, rewards, and termination signals, but no hidden-state labels. It follows a generate–evaluate–refine–plan structure: an LLM proposes executable model components, particle filtering evaluates whether the induced latent beliefs explain the observed trajectories, diagnostic feedback guides model refinement, and the selected model is used for belief-space planning. Unlike state-supervised model induction, *Pinductor* never compares predicted states to ground-truth hidden states. Instead, it scores whether latent rollouts predict observations compatible with the data. Fig. 2 gives an overview of the full pipeline, and Alg. 1 summarizes the procedure. Further methodological details and a discussion of component roles are provided in Appendix A.

4.1 Problem formulation

Consider POMDP models defined in (1), where the state $s_t \in \mathcal{S}$ is latent, the agent takes actions $a_t \in \mathcal{A}$, and receives observations $o_t \in \mathcal{O}$, rewards r_t , and termination signals d_t . The learner is given a dataset $\mathcal{D} = \{\tau_n\}_{n=1}^N$ of N state-free trajectories, collected from offline and/or online interaction,

$$\tau = (o_0^\tau, a_0^\tau, r_1^\tau, d_1^\tau, o_1^\tau, \dots, a_{H_\tau-1}^\tau, r_{H_\tau}^\tau, d_{H_\tau}^\tau, o_{H_\tau}^\tau), \quad (3)$$

where H_τ denotes the horizon of trajectory τ ; thus, H_τ may vary across trajectories. The hidden states $s_{0:H_\tau}^\tau$ are never observed.

The problem: Given $(\mathcal{S}, \mathcal{A}, \mathcal{O}, \gamma)$, the goal is to learn a model

$$m = (\rho_0^m, T^m, O^m, R^m), \quad (4)$$

that explains the realized trajectories and supports downstream tasks. We denote by P^m the full probabilistic model induced by (T^m, O^m, ρ_0^m) , which we optimize with a probabilistic score.

4.2 Model proposal

The LLM receives a natural-language task description, a small offline dataset $\mathcal{D}$, and a code API specifying the relevant state, action, and observation spaces $(\mathcal{S}, \mathcal{A}, \mathcal{O})$. It then generates an executable candidate m defined in (4). We will denote by O_{LLM}^m the observation model generated by the LLM, to distinguish it from the observation model O^m we will finally use.

In our experiments, the offline dataset contains $N = 10$ manually collected trajectories chosen to cover informative parts of each task. Details about data collection can be found in Appendix D.

Figure 2: **Pinductor pipeline.** State-free trajectories, model templates, and a code API prompt the LLM to propose candidate components $\rho_0^m(s)$, $T^m(s' | s, a)$, $O_{LLM}^m(s, a)$, and $R^m(s, a, s')$. For filtering, O_{LLM}^m is softened into the kernel likelihood $O^m(o | s, a)$. A particle filter propagates belief states, reweights them by observation compatibility, and returns likelihood scores and diagnostics for LLM refinement. The selected model is used for planning under partial observability, and online episode feedback is added to the replay buffer—and the loop repeats.

4.3 Belief-based model evaluation

For each candidate m , *Pinductor* evaluates whether predicted observations from latent rollouts generated by P^m can explain the realized observation-action trajectory. A set of K particles indexed by i is sampled from ρ_0^m , propagated through T^m under realized actions by sampling, and scored by comparing a sampled observation $o_{t+1}^i \sim O_{LLM}^m(s_{t+1}^i, a_t)$ against the realized observation o_{t+1} .

For MiniGrid observations $o = (g, \theta, c)$, we compare using a distance over the visible part of the grid g , agent direction θ , and carried object c . In such environments, the agent can pick up and drop objects; c denotes the object, if any, currently carried by the agent at the corresponding timestep.

$$d_{\text{obs}}(o', o) = d_{\text{grid}}(g', g) + \lambda_{\text{dir}} \mathbf{1}[\theta' \neq \theta] + \lambda_{\text{carry}} \mathbf{1}[c' \neq c]. \quad (5)$$

This distance is used to soften the (usually deterministic) LLM-generated code observation model O_{LLM}^m , to furnish a soft observation model where realized observations have positive probability

$$O^m(o_{t+1} | s_{t+1}^i, a_t) \propto \exp(-d_{\text{obs}}(o_{t+1}^i, o_{t+1})/\kappa), \quad (6)$$

where $\kappa > 0$ is a parameter. We can interpret O_{LLM}^m as the mode of O^m and κ as the variance, and the sampling step $o_{t+1}^i \sim O_{LLM}^m(s_{t+1}^i, a_t)$ as sampling the most likely observation under O^m . The full grid-distance definition and constants are given in Appendix A.1. The resulting particle-filtered posterior belief is the distribution of propagated samples s_{t+1}^i reweighted by their likelihood

$$Q_{t+1}^m(s) \propto \sum_{i=1}^K O^m(o_{t+1} | s_{t+1}^i, a_t) \delta_{s_{t+1}^i}(s), \quad (7)$$

Algorithm 1 Belief-based Pinductor refinement

13: end for
14: return  $m^* \sim \text{NEARBEST}(\mathcal{P})$  ▷ (18)–(19)
```

which is exactly the particle-filtered analog of the Bayesian update in (2). Details on particle filtering are available in Appendix B. This yields the expected log likelihood score

$$\mathcal{L}(P^m; \mathcal{D}) = \sum_{\tau \in \mathcal{D}} \sum_{t=0}^{H-1} \mathbb{E}_{s_{t+1} \sim Q_{t+1}^m} [\log O^m(o_{t+1} \mid s_{t+1}^i, a_t)] \quad (8)$$

The summation runs from $t = 0$ to $H - 1$ over the observations o_{t+1} ; the initial observation o_0 is therefore not directly scored, since it has no preceding action and no candidate prediction to compare against. The initial-state distribution ρ_0^m is evaluated indirectly through the first propagated observation $o_1 \sim O_{\text{LLM}}^m(s_1, a_0)$, from propagated states $s_1 \sim T^m(s_0, a_0)$ and $s_0 \sim \rho_0^m$. This score evaluates P^m 's fit of observation-action sequences only; reward and termination errors influence model selection indirectly through the LLM's local diagnostics (see Appendix I for examples).

4.4 Feedback and refinement

Pinductor refines models by turning execution into structured debugging feedback. After a candidate is evaluated, the next prompt does not contain only its scalar score. It also summarizes concrete failure cases: execution errors, trajectory segments with large observation distance, and reward or termination mismatches. The score $S_j = \mathcal{L}(P^{m_j}; \mathcal{D})$ tells the LLM how well the model fits the observed trajectories overall, while the local diagnostics point to code regions that may need repair.

The prompt also includes a disagreement signal for uncertain transition contexts. Since the true hidden transition is unavailable, *Pinductor* uses the transition models generated so far as a committee. Let $\mathcal{C}_j = \{T^{m_1}, \dots, T^{m_j}\}$ denote this committee of transition models. For a belief particle s and action a , each model predicts a next state, yielding votes

$$V_{s,a}(y) = \sum_{T \in \mathcal{C}_j} \mathbf{1}[T(s, a) = y].$$

We summarize disagreement with normalized vote entropy,

$$\text{VE}(s, a) = -\frac{1}{\log |\mathcal{C}_j|} \sum_y \frac{V_{s,a}(y)}{|\mathcal{C}_j|} \log \frac{V_{s,a}(y)}{|\mathcal{C}_j|}, \quad (9)$$

with $\text{VE}(s, a) = 0$ when fewer than two transition models are available. High-entropy contexts are added to the prompt with the corresponding observation context and action. Disagreement is computed on belief particles visited during filtering, using both realized and counterfactual actions, so the LLM sees where the current model family is unsure about the dynamics.

Refinement-by-execution (REx) repeats this process over several rounds. In each round, *Pinductor* refines one existing candidate, asks the LLM for M revised candidates, evaluates them, and adds them

to a persistent candidate pool. The parent candidate is chosen with UCB1: high-scoring candidates are more likely to be refined, but candidates that have been explored less often can also be selected. This creates a refinement tree rather than a single chain of edits. After all rounds, *Pinductor* samples the final model from a near-best set whose scores are within one empirical standard deviation of the best score, avoiding over-commitment to small differences among statistically similar candidates (see (18)–(19), Appendix A.3).

4.5 Planning and online interaction

The selected model m^* is used for belief-space planning. During the episode, the agent maintains a particle belief

$$Q_t(s) \approx P^{m^*}(s_t = s \mid o_{0:t}, a_{0:t-1}), \quad (10)$$

updated using the same distance-kernel observation likelihood as in (14). Actions are chosen by a POMDP planner over this belief state; in our experiments, we use the proposed planner in [14], which is an A*-style belief-space planner. After execution, newly collected trajectories are appended to the dataset, and a fresh REx round is triggered to continue refining the model online.

5 Experiments

5.1 Experimental setup

Environments We evaluate *Pinductor* on MiniGrid environments [15], a controlled family of partially observable domains for testing model discovery under structured dynamics. The suite includes both elementary tasks, such as EMPTY and CORNERS, and more challenging tasks, such as LAVA, FOUR ROOMS, and UNLOCK. This lets us test whether the method can recover useful models in simple settings and whether performance changes as the required transition and reward structure becomes more complex. Details about environments can be found in Appendix E.

Baselines We compare against the LLM-guided POMDP induction method proposed in POMDP Coder [14], which has access to privileged state information during learning, and against two non-LLM baselines: the tabular baseline replaces LLM-generated programs with empirical lookup-table models estimated from the same offline trajectories, while the random baseline samples actions uniformly from a fixed action set independently of the observation history. The tabular baseline is granted privileged access to ground-truth hidden states. The comparison to POMDP Coder is designed to test the central claim of the paper: whether hidden-state supervision can be replaced by belief-based feedback from partial observations. The two LLM-based methods share the same high-level pipeline, the same LLM, and the same evaluation seeds; the main difference is whether the model-learning feedback relies on hidden states or on particle-filtered beliefs. Note that the two LLM-based methods also differ in the number of prompts: *Pinductor* issues a single call returning all four components, while POMDP Coder issues four per-component calls. See Appendix F for details.

Metrics We report average episode reward as the main measure of downstream decision-making performance, and win rate as a complementary success metric that is less sensitive to reward discounting and episode length. To test whether the learned models perform useful inference under partial-observation, we also track belief entropy and belief accuracy relative to the true hidden state during evaluation. These belief metrics are not used as supervision; they are diagnostics for whether the learned model maintains useful latent-state information.

Protocol and implementation details To isolate the effect of removing hidden-state supervision, we match the hyperparameters of *Pinductor* and [14] wherever possible and use the same LLM for both LLM-based methods. For all experiments, except for LLM ablation, both pipelines use Qwen 3.6 Plus [31] as the LLM. In the LLM ablation experiment, we also use Qwen 3 14B [32] and Claude Opus 4.7 [33]. We follow the hyperparameter setting from [14] closely, but reduce the number of offline and online refinement attempts from 25 to 5 after observing no substantial performance change. The belief-space planner includes an entropy coefficient that trades off reward-seeking and information-gathering behavior. We tune this coefficient using the same protocol for all methods that use the planner, and report the best-performing setting for each method. Increasing

this coefficient for the baselines did not improve their performance. More details on experimental variants, hyperparameters, and implementation are given in Appendices D, A.4, and H, respectively.

5.2 Main Results

We evaluate whether *Pinductor* can replace hidden-state supervision with belief-based feedback for LLM POMDP induction and downstream task performance. The central question is not only whether the learned models lead to high downstream reward but also quantifying sample efficiency and useful latent-state inference required for downstream planning under partial observability. We therefore evaluate task performance, belief quality, and sample efficiency across 5 MiniGrid environments of varying complexity. In Appendix G, we additionally report performance in stochastic MiniGrid variants, and sensitivity to the choice of LLM and to the prompt supplied by the user.

Figure 3: **Main task performance.** Mean episode reward (y-axis) and win rate (percentages) across 5 MiniGrid environments; error bars denote 95% percentile confidence intervals. *Pinductor* performs comparably to POMDP Coder [14] despite not accessing privileged hidden state information and learning using only observation–action–reward trajectories. *Pinductor* also outperforms non-LLM model-learning baselines, including a standard tabular POMDP baseline that is granted privileged access to the hidden state. Results are contextualized by a handcrafted ground-truth-model reference.

Pinductor achieves performance comparable to the state-of-the-art LLM baseline while using strictly less information for model induction. As shown in Fig. 3, *Pinductor* also substantially outperforms the non-LLM baselines across the tested MiniGrid environments, including the tabular baseline, indicating that the learned models support effective downstream planning. The apparent differences between *Pinductor* and the privileged-state baseline are small relative to the variability across environments and seeds, especially given the sparse-reward nature of these tasks. We therefore interpret these results as evidence that *Pinductor* can match the performance of a state-access model-induction baseline in this setting, without relying on ground-truth latent states.

Pinductor also maintains meaningful belief states during planning. Its belief becomes more concentrated over the course of an episode and assigns increasing mass to the true hidden state as observations accumulate, which is visible on Fig. 4. This is notable because *Pinductor* receives less supervision during model induction than the state-access baseline, yet still supports the filtering computation needed for planning under partial observability. The smoother entropy reduction comes from our observation-distance kernel (5), which reweights particles by graded observation similarity rather than using the hard exact-match criterion of the state-access baseline. These diagnostics suggest that *Pinductor* is not merely inducing a brittle policy, but learning candidate POMDPs that support informative posterior updates.

The offline sample-efficiency results in Fig. 5 suggest that *Pinductor* does not need many demonstrations to become effective. Even though each trajectory provides less information than in the state-access LLM baseline, *Pinductor* achieves comparable performance at the same sample counts. Moreover, both LLM-based methods reach relatively strong performance after only a few trajectories,

Figure 4: **Belief dynamics.** Left: belief entropy over episode steps. Right: posterior mass on the true hidden state and MAP-belief accuracy. Beliefs become more concentrated and accurate as observations accumulate. *Pinductor* shows smoother entropy reduction due to graded observation-distance reweighting, unlike the state-access baseline’s hard exact matching.

Figure 5: **Offline sample efficiency.** Average episode reward by number of offline demonstration trajectories used for model induction. *Pinductor* reaches strong performance with few trajectories and performs comparably to the state-access LLM baseline despite receiving less information per sample.

suggesting that LLM priors help identify plausible environment structure quickly. In particular, the offline data allows LLM-based methods to propose useful candidate programs, as opposed to constituting enough data to fully identify the transition, observation, and reward models from scratch.

Taken together, these results suggest that LLM-guided POMDP induction can succeed without hidden-state supervision in the tested domains. *Pinductor* performs comparably to the privileged-state access LLM baseline, while retaining the advantages of explicit POMDP models: executable components, belief updates, and downstream planning under partial observability. This indicates that LLM priors, grounded by observation-level feedback, can induce useful models from a small number of offline trajectories.

6 Conclusions and Limitations

Can language-model priors substitute for state supervision when learning POMDPs? Our results suggest they can. *Pinductor* induces executable POMDP world models from a belief-based likelihood signal, without access to hidden states. Despite this, our method matches privileged-state access LLM baselines, significantly outperforms tabular baselines, learns from a small number of trajectories, and produces beliefs that converge on the true latent state.

Still, the current treatment could be improved in several ways. First, our evaluation is restricted to MiniGrid environments, and it remains to test *Pinductor* in related environments and domains with different structure, assessing transfer learning [11], as well as benchmarking with deep RL [28, 34].

Second, the LLM prior currently used to optimize the world model could also be used to optimize other parts of the pipeline, such as the observation distance, the planner, and the demonstration buffer, which are currently fixed. Third, the reliance on LLM API calls induces high variance in *Pinductor* and related methods [14], which future work should aim to reduce.

A Methodological Details

This appendix provides implementation details omitted from the main methodology section for space. Appendix A.1 gives the full distance-kernel likelihood used for model evaluation. Appendix A.2 describes the particle filter and rejuvenation procedure. Appendix A.3 gives additional details on refinement, UCB1 selection, and final model selection.

A.1 Distance-kernel likelihood

The main paper defines the MiniGrid observation distance as

$$d_{\text{obs}}(o', o) = d_{\text{grid}}(g', g) + \lambda_{\text{dir}} \mathbf{1}[\theta' \neq \theta] + \lambda_{\text{carry}} \mathbf{1}[c' \neq c],$$

where g is the partial field-of-view grid, θ is the agent direction, and c is the carried object. The grid component is

$$d_{\text{grid}}(g', g) = \begin{cases} -\log\left(\varepsilon + (1 - \varepsilon) \left(\frac{\sum_{(i,j) \in \mathcal{V}} \mathbf{1}[g'_{ij} = g_{ij}]}{|\mathcal{V}|}\right)^{\alpha_{\text{grid}}}\right), & \text{if at least one visible cell matches,} \\ \infty, & \text{otherwise.} \end{cases} \quad (11)$$

Here, $\mathcal{V}$ denotes the set of visible non-agent cells. We use $\varepsilon = 10^{-6}$ for numerical smoothing and $\alpha_{\text{grid}} = 3$ to penalize weak matches super-linearly. Throughout the experiments, we set $\lambda_{\text{dir}} = \lambda_{\text{carry}} = 1$.

For a candidate model m , let $o^m(s, a) \sim O_{\text{LLM}}^m(s, a)$ denote the observation predicted by the LLM-generated observation program. The induced softened observation model is

$$O^m(o \mid s, a) \propto \exp(-d_{\text{obs}}(o^m(s, a), o)/\kappa), \quad (12)$$

where $\kappa > 0$ controls the sharpness of the likelihood. Smaller values of κ penalize observation mismatches more severely, while larger values make the score more tolerant to near-misses.

The particle-filtered kernel score to evaluate probabilistic models P^m used in the main paper is a posterior expected kernel log-likelihood:

$$\mathcal{L}(P^m; \mathcal{D}) = \sum_{\tau \in \mathcal{D}} \sum_{t=0}^{H-1} \mathbb{E}_{s_{t+1} \sim Q_{t+1}^{m, \tau}} [\log O^m(o_{t+1}^\tau \mid s_{t+1}, a_t^\tau)], \quad (13)$$

using the softened observation model above, up to fixed normalization constants. This objective is used only as a differentiability-free model-ranking signal. It does not estimate the log marginal likelihood.

A.2 Particle filtering and rejuvenation

For each trajectory τ , the particle filter maintains a set of K particles representing the belief $Q_t^{m, \tau}$. Particles are initialized from the candidate initial-state model:

$$s_0^i \sim \rho_0^m, \quad i = 1, \dots, K.$$

At each timestep, particles are propagated through the candidate transition model:

$$s_{t+1}^i \sim T^m(\cdot \mid s_t^i, a_t^\tau).$$

The LLM-generated observation program then produces

$$o_{t+1}^i \sim O_{\text{LLM}}^m(s_{t+1}^i, a_t^\tau),$$

and the particle receives kernel weight

$$w_{t+1}^i \propto O^m(o_{t+1}^\tau \mid s_{t+1}^i, a_t^\tau) \propto \exp(-d_{\text{obs}}(o_{t+1}^i, o_{t+1}^\tau)/\kappa). \quad (14)$$

Weights are normalized to obtain the particle belief $Q_{t+1}^{m,\tau}$. We resample the belief after every observation update: weights in (14) carry only the current step’s kernel likelihood (not a cumulative product), and the belief passed to step $t + 1$ is reconstructed from these weights as integer particle counts proportional to w_{t+1}^i . This makes the per-step expression a valid posterior approximation under bootstrap-style resampling. The effective sample size is

$$\text{ESS}_{t+1} = \frac{1}{\sum_i (\bar{w}_{t+1}^i)^2}, \quad (15)$$

where $\bar{w}_{t+1}^i$ are weights normalized to sum to 1.

We trigger belief rejuvenation when the total post-observation weight drops below K (i.e., when the kernel-weighted particle mass cannot represent a full population). When this happens, we draw fresh particles from ρ_0^m , roll them forward through the recorded action history $a_{0:t}^\tau$, and keep rollouts with probability proportional to their cumulative kernel likelihood:

$$\prod_{\ell=0}^t \exp(-d_{\text{obs}}(O_{\text{LLM}}^m(s_{\ell+1}, a_\ell^\tau), o_{\ell+1}^\tau)/\kappa). \quad (16)$$

This procedure reintroduces diversity when the particle population collapses, while still conditioning on the observed observation-action history. Note that under rejuvenation the particle population can transiently exceed the configured K particles, so the reported per-step ESS values in refinement diagnostics may temporarily exceed K ; the score itself remains well-defined since it depends only on the normalised weights.

In all experiments, we use $K = 10$ particles and $\kappa = 0.2$. The same filtering procedure is used for both offline model evaluation and online belief tracking during planning. See Appendix B for general background on particle filtering.

A.3 Feedback, refinement, and candidate selection

Each evaluated candidate model produces three feedback objects used in the next refinement prompt.

First, the scalar score

$$S_j = \mathcal{L}(P^{m_j}; \mathcal{D})$$

summarizes global compatibility with the offline trajectories. This score is used both for UCB1 parent selection during refinement and for final model selection.

Second, local diagnostics D_j summarize failure modes. These include runtime errors, invalid outputs, low-likelihood trajectory segments, observation contexts where the predicted observation differs substantially from the recorded observation, and reward or termination mismatches. These diagnostics are included in the refinement prompt so that the LLM can make targeted edits to the generated code rather than regenerate the entire model from scratch. Candidate models that raise execution errors during particle filtering receive $S_j = -\infty$ and are excluded from the near-best set $\mathcal{N}$; they remain in the persistent pool $\mathcal{P}$ so their diagnostics inform the next refinement prompt, but cannot be sampled as the final model.

Third, the QBC signal Q_j summarizes high-disagreement transition contexts. For the committee

$$\mathcal{C}_j = \{T^{m_1}, \dots, T^{m_j}\},$$

we compute normalized vote entropy as in (9). The disagreement score is computed on particles sampled from the filtering beliefs. We then include the highest-disagreement contexts in the prompt, together with the corresponding observation context and action. The QBC signal is diagnostic only: it is not added to the model-selection objective.

UCB1 parent selection The candidate population is maintained as a persistent refinement tree. At each REx round, *Pinductor* selects a parent node p according to UCB1:

$$\text{UCB}(p) = \bar{S}(p) + c_{\text{ucb}} \sqrt{\frac{\log n_{\text{parent}(p)}}{n_p + 1}}, \quad (17)$$

where $\bar{S}(p)$ is the mean kernel score of candidates generated from node p , n_p is the number of times p has been expanded, and $n_{\text{parent}(p)}$ is the visit count of its parent. If the candidate pool is empty, the root prompt is used. This tree-structured expansion allows refinement to concentrate on promising candidate families while preserving an exploration bonus for less-expanded branches. We use a smoothed denominator ($n_p + 1$) inside the square root, so the exploration bonus stays finite even for unexpanded nodes ($n_p = 0$). Fresh nodes still receive the largest bonus (no prior visits to amortize) but cannot dominate the score outright, allowing a sibling with a good $\bar{S}$ to overtake them. The exploration constant is $c_{\text{ucb}} = 1.0$ in all experiments.

Final selection After all REx rounds, the final model is sampled from the near-best set

$$\mathcal{N} = \{j : S_j \geq S^* - \text{std}(\{S_{j'}\})\}, \quad S^* = \max_j S_j. \quad (18)$$

Sampling from this set rather than taking a hard argmax avoids over-committing to small differences in the noisy particle-filtered score. The final selector is

$$\Pr(m^* = m_j) = \frac{\exp(S_j/T)}{\sum_{k \in \mathcal{N}} \exp(S_k/T)}, \quad j \in \mathcal{N}. \quad (19)$$

We use $T = 0.1$. As $T \rightarrow 0$, this recovers hard argmax selection within the near-best set. Since $\mathcal{N}$ always contains the current best-scoring candidate, the procedure preserves access to the best model found while allowing selection of a structurally different candidate with statistically similar score.

A.4 Hyperparameters

Unless otherwise stated, all experiments use $K = 10$ particles, bandwidth $\kappa = 0.2$ (for *Pinductor*), $M = 5$ candidates per REx round, final-selection temperature $T = 0.1$, direction and carried-object penalties $\lambda_{\text{dir}} = \lambda_{\text{carry}} = 1$ (for *Pinductor*), grid-distance exponent $\alpha_{\text{grid}} = 3$ (for *Pinductor*), smoothing constant $\varepsilon = 10^{-6}$, and a planner budget of 5,000 belief-state expansions.

The only notable difference between both setups is the entropy coefficient. For *Pinductor*, increasing the value of this coefficient led to better exploration and higher rewards on average, while it did not lead to any significant performance gain for POMDP Coder. In the experiments, *Pinductor* used a coefficient of 1.0, and POMDP Coder used a coefficient of 0 (which is the default value in its own implementation).

A.5 Role of the components

Pinductor separates four roles that are often entangled in partially observable model learning. The LLM provides a structured prior over executable model programs. Particle filtering provides the learning signal by asking whether the candidate model can maintain plausible latent trajectories that explain partial observations. The distance kernel makes this evaluation robust to mismatches in high-dimensional partial observations. QBC disagreement identifies transition contexts where plausible candidate models make incompatible predictions. Finally, belief-space planning uses the selected model in the same representation used for evaluation, closing the loop between model proposal, latent-state inference, diagnostic refinement, and action selection.

B Particle Filtering Background

Particle filtering is a sequential Monte Carlo method for approximately maintaining beliefs over latent states in partially observable dynamical systems. In a POMDP with transition model T and observation model O , the exact Bayes filter updates a belief $Q_t(s_t)$ by first predicting through the transition model and then conditioning on the new observation. After action a_t , the predictive belief is

$$\bar{Q}_{t+1}(s') = \sum_{s \in \mathcal{S}} T(s' | s, a_t) Q_t(s),$$

and the observation update is

$$Q_{t+1}(s') \propto \sum_{s' \in \mathcal{S}} O(o_{t+1} | s', a_t) \bar{Q}_{t+1}(s').$$

Particle filtering approximates this belief with a finite set of weighted particles $\{(s_t^i, w_t^i)\}_{i=1}^K$. In the bootstrap particle filter, particles are propagated through the transition model,

$$s_{t+1}^i \sim T(\cdot | s_t^i, a_t),$$

and reweighted by the observation likelihood,

$$w_{t+1}^i \propto O(o_{t+1} | s_{t+1}^i, a_t).$$

Weights are then normalized, and resampling may be used to avoid degeneracy when most particle mass concentrates on a small number of particles.

Pinductor follows this basic filtering structure, but adapts it to executable LLM-generated POMDP programs. The candidate transition and observation models may be deterministic programs rather than soft probability distributions. After propagating a particle through the candidate transition model, *Pinductor* obtains a predicted observation

$$o_{t+1}^i \sim O_{\text{LLM}}^m(s_{t+1}^i, a_t),$$

and compares it to the observed o_{t+1} using the observation distance d_{obs} . This distance induces the kernel weight

$$w_{t+1}^i \propto O^m(o_{t+1} | s_{t+1}^i, a_t) \propto \exp\left(-\frac{d_{\text{obs}}(o_{t+1}^i, o_{t+1})}{\kappa}\right),$$

which plays the role of the observation likelihood in the filtering update. Thus, the update remains a standard particle-filtering update in form, where the LLM-generated likelihood is softened into a distance-kernel likelihood. This allows *Pinductor* to assign positive likelihood to any realized observation, enabling learning, in spite of the fact that the LLM-generated observation model may be deterministic.

The implementation also uses a rejuvenation step when particle mass becomes too small. Rather than relying only on particles propagated from the previous belief, *Pinductor* samples additional candidate initial states from ρ_0^m , rolls them forward through the observed action history, and keeps them with weight proportional to their cumulative kernel likelihood along the trajectory. This replenishes the belief with latent trajectories that remain compatible with the observations, which is important because LLM-generated models can be imperfect and a strict particle filter can otherwise collapse after successive mismatches.

After reweighting and rejuvenation, the weighted particles define the model’s filtered belief Q_t^m . The same belief is used both for scoring candidate models and for downstream planning. This is central to *Pinductor*: the evaluation does not ask whether any particle matches a privileged hidden state, but whether the candidate model can maintain a belief whose latent trajectories explain the observation stream.

C Distance-Kernel Likelihood and Energy Interpretation

Pinductor evaluates executable candidate models in a setting where the latent state is never observed. We provide some clarifications for the scoring objective used in the main text (8) and its connection to both likelihood-based filtering and energy-based inference.

Let m be a candidate executable POMDP model. Given a latent state s_{t+1} and action a_t , the candidate observation program predicts observations

$$o_{t+1} \sim O_{\text{LLM}}^m(s_{t+1}, a_t).$$

Since in practice the LLM generated program is usually deterministic, it usually defines a Dirac likelihood, which causes problems for our objective since most realized observations have zero mass under this model. To circumvent this problem, *Pinductor* defines an observation compatibility energy

$$E_m(s_{t+1}, o_{t+1}, a_t) = d_{\text{obs}}(O_{\text{LLM}}^m(s_{t+1}, a_t), o_{t+1}),$$

where d_{obs} is the task-specific observation distance. This energy induces an unnormalized distance-kernel likelihood

$$K_\kappa^m(o_{t+1} \mid s_{t+1}, a_t) = \exp\left(-\frac{E_m(s_{t+1}, o_{t+1}, a_t)}{\kappa}\right),$$

with bandwidth $\kappa > 0$. Observations that are better explained by the candidate state and realized action receive higher kernel values, while observations far from the candidate prediction receive exponentially smaller values. If desired, this kernel can be normalized, giving the soft likelihood model $O^m(o_{t+1} \mid s_{t+1}, a_t) \propto K_\kappa^m(o_{t+1} \mid s_{t+1}, a_t)$. Let $Q_t^{m,\tau}$ denote the particle belief at time t , induced by model m after observing trajectory τ . After action a_t^τ , the predictive belief is obtained by propagating particles through the candidate transition model:

$$\bar{Q}_{t+1}^{m,\tau}(s') = \sum_{s \in \mathcal{S}} T^m(s' \mid s, a_t^\tau) Q_t^{m,\tau}(s).$$

This is simply the push-forward of the particle set through T^m and constitutes a prior about the state at time $t+1$. The Bayesian update (2) proceeds to reweight the prior into the posterior. This proceeds by reweighting by the likelihood of realized observations o_{t+1}^τ :

$$Q_{t+1}^{m,\tau}(s') \propto \sum_{s' \in \mathcal{S}} \bar{Q}_{t+1}^{m,\tau}(s') O^m(o_{t+1}^\tau \mid s', a_t^\tau).$$

Note that in practice we sum over all particles as opposed to all possible states (as states that are not assigned a particle have prior probability zero), which makes the number of summands tractable. Equivalently, each particle in $\bar{Q}_{t+1}^{m,\tau}$ receives weight

$$w_{t+1}^i \propto O^m(o_{t+1}^\tau \mid s_{t+1}^i, a_t^\tau) \propto \exp\left(-\frac{d_{\text{obs}}(O_{\text{LLM}}^m(s_{t+1}^i, a_t^\tau), o_{t+1}^\tau)}{\kappa}\right).$$

This is exactly a Boltzmann reweighting with energy $E_m(s_{t+1}, o_{t+1}^\tau, a_t^\tau)$ and temperature κ : low-energy particles receive high posterior mass, while high-energy particles are suppressed.

The model ranking score used by *Pinductor* is the filtered expected log soft-observation likelihood:

$$\mathcal{L}(P^m; \mathcal{D}) = \sum_{\tau \in \mathcal{D}} \sum_{t=0}^{H-1} \mathbb{E}_{s_{t+1} \sim Q_{t+1}^{m,\tau}} [\log O^m(o_{t+1}^\tau \mid s_{t+1}, a_t^\tau)].$$

Substituting the unnormalized kernel gives, up to additive constants independent of m ,

$$\mathcal{L}(P^m; \mathcal{D}) = -\frac{1}{\kappa} \sum_{\tau \in \mathcal{D}} \sum_{t=0}^{H-1} \mathbb{E}_{s_{t+1} \sim Q_{t+1}^{m,\tau}} [d_{\text{obs}}(O_{\text{LLM}}^m(s_{t+1}, a_t^\tau), o_{t+1}^\tau)].$$

The $1/\kappa$ prefactor is a positive constant that does not affect $\arg \max_m$ at fixed κ , so maximizing the score is equivalent to minimizing the expected observation energy under the filtered belief induced by

the candidate model. Note however, that, since we sample models through a softmax (19), κ does play the role of a temperature parameter there jointly with T . Also, and unlike T , κ controls the variance of the soft likelihood and therefore shapes the belief $Q_{t+1}^{m,\tau}$ under which the expectation is taken: it is a genuine hyperparameter of the method, not a cosmetic scale.

The resulting score has three useful properties for strict POMDP induction. First, it is computable from observations, actions, rewards, and termination signals without access to hidden-state labels. Second, it is defined for executable programs, including deterministic transition and observation functions, because it only requires simulating latent particles and comparing predicted observations to observed ones. Third, it is aligned with the belief state used for planning: a candidate model scores well only if its own filtering process maintains latent particles that explain the observed trajectory. In this sense, the score evaluates the operational object needed by the planner, namely the model-induced belief, rather than an oracle comparison to privileged states.

We therefore view $\mathcal{L}(P^m; \mathcal{D})$ as a particle-filtered expected likelihood, or equivalently as a negative expected observation energy under posterior beliefs. It should not be read as a variational ELBO or as an exact marginal likelihood.

D Experimental details

D.1 Stochastic MiniGrid variants

We use stochastic MiniGrid variants to test whether model induction remains robust when the same task can instantiate into multiple concrete layouts. We do not include Corners in this experiment, since this environment is already stochastic: the goal corner, agent starting position, and agent direction vary across episodes. Lava and Unlock already contain some stochasticity, but we increase the episode-level variation in the quantities that are relevant to model learning. In the standard Lava environment, the lava wall position and gap position vary across episodes; we increase the stochasticity to the agent’s starting position and direction, and to the goal position. In the standard Unlock environment, the agent’s start position and direction, as well as the key position, vary across episodes; we increase the stochasticity to the wall and goal position. These variants make it harder for a generated model to memorize a single layout and instead require it to represent the latent structure of the task.

D.2 Offline datasets

Our offline datasets differ from those used in the original POMDP Coder paper [14]. The original datasets were composed of oracle trajectories, i.e. successful demonstrations generated by an expert policy. This provides clean examples of how to solve the task, but it gives little or no evidence about failure modes. For instance, in Lava, a success-only dataset may never show what happens when the agent walks into lava, so the learner must infer this terminal event from the environment description or prior knowledge rather than from data.

We therefore construct the offline datasets by mixing successful and unsuccessful episodes, including failures and timeouts when available. Empirically, this improved performance in some environments. The goal is to increase behavioral diversity in the replay buffer and encourage the LLM to learn transition, observation, and reward structure rather than memorize the oracle trajectory distribution. In particular, mixed datasets expose both positive terminal events, such as reaching the goal, and negative or zero-reward outcomes, such as entering lava or failing to complete the task within the horizon.

Both LLM-based POMDP methods used in the paper use the same datasets for all experiments to ensure fair comparison.

D.3 Ground-truth model baselines

In the plots, “Ground-Truth Models” refers to runs in which the learned model components are replaced by the manually specified models from [14]. These models were manually verified and serve as a baseline for good model quality. However, they should not be interpreted as an optimal-policy oracle: the models are not guaranteed to be optimal for every environment instance, and

the downstream planner remains approximate. Consequently, a generated model can sometimes outperform the ground-truth-model baseline in terms of realized reward.

For the Ground-Truth baseline, the planning stage is similar to POMDP Coder; the only difference is that the models are handcrafted.

D.4 Environment descriptions and natural-language sweep

For the main experiments, we provide the LLM with the strongest environment description level, denoted L3 in Fig. 11. The natural-language sweep varies how much prior information the LLM receives, from no description at L0 to the full task description at L3. Thus, the sweep measures sensitivity to the LLM’s environment prior: moving from L0 to L3 gives the model increasingly explicit information about the environment and the preferred POMDP structure. In all main-result experiments, we use L3.

Below, we list the exact natural-language descriptions used at each level. The description text provided to the LLM is shown in quotation marks and italics.

CORNERS

L0: No natural-language environment description.

L1: *“10x10 grid.”*

L2: *“10x10 grid with boundary walls. Goal is in a corner of the grid. Agent starts at an interior position.”*

L3: *“10x10 grid with boundary walls. Goal is placed in a random corner of the grid. Agent starts at a random interior position with random direction. No obstacles. Both agent start and goal corner vary between episodes.”*

LAVA

L0: No natural-language environment description.

L1: *“10x10 grid with lava.”*

L2: *“10x10 grid with boundary walls. A vertical wall of lava with one passable gap. Agent starts at (1, 1). Goal is at the bottom-right corner.”*

L3: *“10x10 grid with boundary walls. A vertical wall of lava spans most of one column with exactly one gap to pass through. Agent starts at (1, 1). Goal is at the bottom-right corner. The lava column position and gap position vary between episodes.”*

FOURROOMS

L0: No natural-language environment description.

L1: *“19x19 grid.”*

L2: *“19x19 grid divided into 4 rooms by internal walls, each connected by one doorway. Agent and goal are placed in different rooms.”*

L3: *“19x19 grid divided into 4 rooms by internal walls, each room connected by one doorway. Agent and goal are placed at random positions in different rooms. Room layout is fixed, but agent start position, direction, and goal position vary between episodes.”*

UNLOCK

L0: No natural-language environment description.

L1: *“Grid world with a locked door.”*

L2: *“Grid world with boundary walls and a locked door separating the map into two sections. A key is in the accessible section; the goal is behind the locked door.”*

L3: *“Grid world with boundary walls and a locked door separating the map into two sections. A key is placed in the accessible section, and the goal is located behind the locked door. Agent starts in the initial section with random position and direction. The room layout is fixed, while agent start position, key position, and goal position vary between episodes.”*

E General details on environments

We evaluate on five deterministic MiniGrid environments. For the interesting environments, we illustrate what each method observes at the start of an episode and at the moment the agent reaches the reward, by replaying the same recorded *Pinductor* trajectory under both observation models. *Pinductor* only ever sees a 3×3 partial field of view (the current FOV is highlighted in red, while previously visited cells remain visible as the cumulative trajectory; cells never visited are masked as unseen). The main baseline [14] has post-hoc access to the full underlying state, shown unmasked.

Corners (CornerGoalRandom-Empty-10x10-v0) A 10×10 empty room with the goal placed uniformly at random in one of the four corners. The empty room is rotationally near-symmetric, so a small partial FOV produces almost identical observations from each corner (Fig. 6). The main difficulty is therefore *position disambiguation*: the agent must navigate while reasoning about *which* corner contains the goal under substantial pose ambiguity.

Figure 6: **Corners** – observability comparison on a winning episode.

Lava (MyMiniGrid-LavaWall-v0) A room split by a wall of lava with a single safe passage (Fig. 7). Stepping on a lava cell terminates the episode with zero reward. The difficulty is *learning the terminal hazard*: a model that fails to encode lava as a terminating, low-reward cell will produce a planner that takes the apparent shortcut and dies. The reward signal alone is sparse, so the model must combine the natural-language description and trajectory cues to identify lava semantics.

Figure 7: **Lava** – observability comparison on a winning episode.

Four Rooms (MyMiniGrid-FourRooms-v0) Four rooms connected by narrow gap doorways, with the goal placed at a random position that varies across episodes (Fig. 8). The difficulty is *long-horizon navigation*: episodes are long, the agent must commit to traversing specific doorways without seeing the goal, and the random goal placement prevents the model from collapsing to a fixed plan. The 3×3 FOV makes each doorway choice a near-blind decision conditioned on belief over goal location.

Figure 8: **Four Rooms** – observability comparison on a winning episode.

Unlock (MyUnlockEnv-v0) An 11×6 grid split into two 6×6 rooms by a wall pierced by a single locked door at column 5 (Fig. 9). A key, whose colour matches the door, lies somewhere in the accessible left room; the goal sits at a fixed position behind the locked door. The difficulty is *compositional structure*: the agent must execute a multi-step plan (locate key $\rightarrow$ pick up $\rightarrow$ unlock door $\rightarrow$ traverse $\rightarrow$ reach goal), each phase conditioned on the previous one. A correct world model must encode the carrying channel, the door-state transition under the unlock action, and the colour-matching constraint between key and door, all from observation traces alone.

Figure 9: **Unlock** – observability comparison on a winning episode.

F General details on baselines

F.1 Tabular Baseline

The tabular baseline learns each of the four components of the POMDP separately as frequency tables from the offline dataset. For the *initial model*, it stores the initial states of each episode and then samples proportionally from the frequency at inference-time:

$$\hat{P}_0(s) = \frac{\#\{e : s_0^e = s\}}{|\mathcal{D}|}$$

For the *transition model*, it counts the number of times each transition (s, a, s') occurs in the dataset, and similarly samples proportionally at inference-time:

$$\hat{P}(s' | s, a) = \frac{\#(s, a, s') \in \mathcal{D}}{\#(s, a) \in \mathcal{D}}$$

For the *reward model*, it accumulates the sum of rewards and terminations for each (s, a, s') triple, and returns the mean reward and Bernoulli-sampled termination at inference-time:

$$\hat{R}(s, a, s') = \frac{\sum r_t}{\#\mathcal{D}[s, a, s']} \quad \hat{P}_{\text{term}}(s, a, s') = \frac{\#\text{done}}{\#\mathcal{D}[s, a, s']}$$

For the *observation model*, it counts the number of times each observation o is observed after (s', a) pairs, and samples proportionally at inference-time:

$$\hat{P}(o | s', a) = \frac{\#(s', a, o) \in \mathcal{D}}{\#(s', a) \in \mathcal{D}}$$

In all cases, unseen conditions fall back to a silent default. Note that the tabular baseline requires access to privileged information about the hidden state.

G Ablations and Additional Results

Performance analysis as a function of LLM choice Table 1 evaluates how the choice of LLM affects our pipeline when the offline buffer, refinement budget, particle filter, planner, and prompts are held fixed. The results suggest a threshold-like dependence on model quality rather than a smooth scaling trend. With sparse rewards, weaker models often fail to infer a sufficiently correct executable model and therefore obtain near-zero downstream reward. Once the LLM is capable enough to recover the key environment dynamics and reward structure, performance jumps sharply and then largely saturates.

This pattern is clearest in LAVA: Qwen3 14B obtains low reward, while Qwen3.6 Plus and Claude Opus 4.7 both reach similar high performance. In UNLOCK, the same qualitative trend appears, although the task remains harder overall: the weaker model fails, while the two stronger models obtain comparable nonzero performance. These results indicate that, under sparse rewards, LLM capability primarily matters in crossing the threshold needed to synthesize a usable world model; beyond that point, additional model strength yields smaller gains in downstream planning performance.

Table 1: **LLM ablation.** Mean episode reward $\pm$ 95% CI ($n = 10$ seeds) on LAVA and UNLOCK when varying only the LLM used to propose model code. Win rate (reward > 0.05) is shown in parentheses. **Avg.** is the mean of the two task rewards.

LLM	Lava		Unlock		Avg.	
	Reward	Win	Reward	Win	Reward	Win
Qwen3 14B	0.07 $\pm$ 0.14	10%	0.00 $\pm$ 0.00	0%	0.04 $\downarrow$	5%
Qwen3.6 Plus	0.59 $\pm$ 0.10	83%	0.36 $\pm$ 0.14	53%	0.48 $\uparrow$	68%
Claude Opus 4.7	0.61 $\pm$ 0.07	87%	0.37 $\pm$ 0.22	50%	0.49 $\uparrow$	68%
<i>Average</i>	0.43	60%	0.24	34%	0.33	47%

Robustness to stochastic environments Fig. 10 tests whether the method remains useful when the environment departs from deterministic dynamics. Performance drops relative to the deterministic versions, as expected, but the comparison with the state-access LLM baseline suggests that removing hidden-state supervision does not by itself cause a disproportionate loss under stochasticity. This indicates that the belief-based evaluation signal can still guide model induction when observations and transitions are less predictable.

Figure 10: **Robustness to stochastic environments.** Average episode reward and win rate in stochastic MiniGrid variants. *Pinductor* remains comparable to the state-access LLM baseline, suggesting that observation-only model induction remains effective under stochastic transitions and observations.

Prompt-information ablation Fig. 11 tests how much natural-language information the LLM needs in order to propose useful model hypotheses. We sweep four prompt levels: L0 (none), L1 (minimal grid-size information), L2 (structural layout and goal information), and L3 (the full description used in the main experiments). The pattern is task dependent: some environments can be partially recovered from the LLM prior and trajectories alone, while others require structural cues before performance improves. This supports the view that *Pinductor* relies on a combination of semantic priors and empirical feedback; when the prior is underspecified, additional task structure in the prompt can make the model search much more effective.

Figure 11: **Prompt-information ablation.** Average episode reward as the natural-language prompt is varied from no task description (L0) to the full description used in main experiments (L3). Performance is task dependent, indicating that *Pinductor* combines LLM priors with trajectory feedback and benefits from structural task cues when the prior alone is underspecified.

Semantic-information ablation Fig. 12 tests whether performance comes merely from fitting trajectories or also from the semantic content available to the LLM. Replacing meaningful environment and object names with less informative labels reduces performance across environments, indicating that the LLM uses semantic cues to form better initial hypotheses and refinements. This is consistent with the central mechanism of the paper: language models act as structured priors, while the filtering objective uses data to evaluate and correct those priors.

Figure 12: **Semantic-information ablation.** Average episode reward when meaningful environment and object names are replaced with less informative labels. Performance drops across environments, suggesting that *Pinductor* uses semantic cues as structured priors rather than only fitting trajectories.

H Implementation and Reproducibility Details

H.1 Computational Resources

Table 2 reports the wall-clock time required to run one seed at $N = 10$ demonstrations. Since runtime can have heavy-tailed outliers, especially in environments where incorrect model hypotheses lead to longer inference traces, we report the median and interquartile range across seeds rather than the mean and standard deviation.

Table 2: Wall-clock time per run at $N = 10$ demonstrations. Values are median [IQR] minutes over seeds.

Environment	POMDP Coder	Pinductor (ours)	Tabular
Corners	12.0 [9.9, 15.6]	22.0 [14.0, 28.8]	0.3 [0.2, 0.3]
Lava	17.2 [15.1, 21.7]	33.5 [22.1, 44.2]	1.5 [1.2, 1.7]
Unlock	88.2 [74.7, 100.4]	90.7 [72.3, 98.1]	0.6 [0.6, 0.7]
Four rooms	51.1 [18.3, 77.0]	51.2 [41.8, 58.5]	2.0 [1.9, 2.1]

Table 3 summarizes the compute environment used for the experiments. All runs were executed on a single local CPU workstation without GPU acceleration; LLM calls were made through OpenRouter. Wall-clock measurements therefore include both local computation and remote LLM API latency.

Table 3: Compute environment used for the experiments.

Resource	Specification
CPU	AMD Ryzen 7 7800X3D, 8 cores / 16 threads
Memory	30 GiB RAM
GPU	None
Operating system	Ubuntu 24.04
Execution environment	Single local workstation
LLM API provider	OpenRouter

H.2 Randomness Control

Randomness is controlled at the level of both the run and the evaluation episode. Each experimental condition is evaluated over a fixed set of 10 run seeds. At the start of a run, we seed the Python, NumPy, and Torch random number generators with the run seed. Before each evaluation episode, we reset the Python and NumPy RNGs using a deterministic episode seed, and reset the environment with the same seed. This ensures that, for a given run seed and episode index, all methods are evaluated on the same initial environment instance. For LLM-based methods, we also pass the run seed as the LLM seed when querying the model provider, making LLM sampling as reproducible as the provider allows. We log the served backend and model identity for post-hoc diagnosis.

The error bars in our reward and belief figures capture variability across random seeds. Because the 3 evaluation episodes associated with a single run seed are not independent, we first average the metric within each seed and then compute uncertainty over the resulting 10 seed-level estimates. Unless otherwise stated, error bars denote 95% percentile bootstrap confidence intervals over these seed-level estimates. Specifically, we resample the 10 seed-level estimates with replacement, compute the mean for each bootstrap sample, and report the 2.5th and 97.5th percentiles of the bootstrap distribution.

We use bootstrap intervals rather than normal-theory intervals because many of our metrics are bounded and can lie near the boundary, for example rewards or win rates close to 0 or 1. In such cases, the usual Gaussian approximation $1.96 \cdot s/\sqrt{n}$ can produce misleading intervals, especially with only $n = 10$ independent seeds. The bootstrap procedure avoids assuming an approximately normal sampling distribution and better reflects the empirical variability induced by the random seed. For wall-clock time, which can be heavy-tailed, we instead report the median and interquartile range across seeds.

H.3 Licenses and Third-Party Assets

MiniGrid [15] is used under the Apache 2.0 license. LLM APIs (Claude, Qwen) are used under their respective commercial terms of service. Code from Curtis et al. [14] is reused with citation; their repository (https://github.com/aidan-curtis/pomdp_coder) does not specify an explicit license.

I Details on prompting methods

To make the methodological difference between **Pinductor** and **Curtis et al.** [14] concrete, we reproduce verbatim inputs and outputs of (i) the offline initial proposal and (ii) one refinement iteration. Listings are kept in flow (no figure floats) so each exchange appears exactly where it is referenced; long demonstration blocks are truncated with explicit [...] placeholders to keep the appendix readable. We keep the prompt verbatim from Curtis et al. including a templating quirk in their original release where the per-component instructions read “*implement the reward function*” regardless of the actual {model_name}; the LLM correctly infers the intended target from the surrounding context.

Both methods follow a generate–evaluate–refine loop with two regimes: an *offline* REx loop on the demonstration buffer, and an *online* regime triggered after each evaluation episode. The two methods differ on three axes that are visible below: (i) *state access* – *Pinductor*’s prompts only contain observation–action–reward sequences, while Curtis et al.’s prompts embed Input MinigridState/Output MinigridState tuples drawn from privileged hidden states; (ii) *granularity* – *Pinductor* issues *one joint call* returning (ρ_0, T, O, R) at each REx step, whereas Curtis et al. issues *four separate calls* per step (one per component, instantiating the same template with a different model_name); we show their transition_func call as representative; (iii) *feedback signal* – at refinement time, *Pinductor* injects the particle-filter kernel score and per-step disagreement diagnostics, while Curtis et al. injects state-level disagreements between the candidate model’s predictions and the recorded hidden states. Our ‘no hidden state’ claim refers to state values during trajectories: the LLM is given the state schema (field names + types) as part of the code API but never their realised values during training or evaluation.

Curtis et al. ships an online_update_models hook that calls the same REx procedure as the offline loop, using the same prompt template (po_model_refining.txt). On the deterministic MiniGrid bench, their online hook is gated by a coverage check that skips the update when new-episode coverage does not strictly degrade, so the online refinement calls are not exercised on these runs. The example we show below for Curtis et al.’s online refinement therefore reuses an iteration-1 REx refinement call, which is bit-identical to what the online hook would emit when triggered. *Pinductor*’s online example is a true post-episode 0 refinement call from a recorded run.

I.1 Initial model proposal (offline, iter 0, LAVA)

Pinductor — INPUT (joint, partial-obs)

```
#define system
You are a robot exploring its environment through partial observations.

ENVIRONMENT
-----
10x10 grid with boundary walls. A vertical wall of lava spans most of one column with exactly one gap
to pass through. Agent starts at (1,1). Goal is at the bottom-right corner. The lava column
position and gap position VARY between episodes.

GOAL
----

Your task is to model the distribution of initial states, observations, transitions, and rewards in
Python.
You need to implement code that captures the dynamics observed in the data below.

IMPORTANT CONSTRAINTS
-----
- You have NO access to the true state - it is hidden.
- You only observe the agent’s partial field of view after each action.
```

- Your models must explain how observations change when actions are taken.
- Observations are partial views of a persistent world. Successive observations are snapshots of the same underlying state evolving under your transition model, not independent frames. Keep in mind that the agent itself occupies space in its view, which can momentarily mask part of what is otherwise stable.

You have no access to the true states as they stay hidden.

Below are samples of Actions and Observations from the environment for different episodes. Each Input (action) is followed by the Output (observation) received after taking that action. You should model the different models that explain the observed dynamics.

Note: The samples do NOT show the underlying State because it is hidden.

Observation format: Each observation is a grid that represents the agent's field of view (point of view). The agent is always at the same fixed position within this grid. The rest of the grid cells represent the environment as perceived by the agent at that particular step. The grid thus encodes what the agent sees in front of it at each step.

Use the samples and the environment specifications below to make an informed guess about the different models.

You do not observe true initial states directly. Infer the initial-state distribution from the environment description and from the first observation of each episode. 'initial_func' should sample a plausible hidden state consistent with those clues.

OBSERVED DATA

--- Episode 1 ---

```
MinigridObservation(image=
[[ 2  2  2]
 [ 1  1 12]
 [ 1  1 1]], dir=0, carrying=None)
```

```

INSTRUCTIONS

 1. First, explain in plain English what you believe the dynamics are:
 - Which hidden variables are randomized at the start of each episode?
 - How does the agent's view change when it moves or turns?
 - What objects exist and how does the agent interact with them?
 - What actions succeed or fail, and why?
 2. Then, implement the initial_func, observation_func, transition_func, reward_func, and initial_func functions.

Rules:
 - You must implement the initial_func, observation_func, transition_func, reward_func, and initial_func functions.

- Create helper functions only INSIDE the scope of the initial_func, observation_func, transition_func, reward_func, and initial_func functions.
- Do not create new classes or import new modules.
- Do not overfit to specific sample indices - use general rules.
- Put the initial_func, observation_func, transition_func, reward_func, and initial_func functions in a python code block.

Generalization principles

Your goal is to build a **world model**: a compact, general description of how the environment behaves. The samples below are a few draws from an infinite distribution of layouts; the model you write must work on draws you have never seen.

1. **Rules over memorization.** Express conditions on the semantic content of states, not on the literal arrays present in the samples. A rule that hard-codes a specific layout fragment will break on the next draw.
2. **Cover the space, not the sample.** Enumerate every plausible case the environment can produce and decide what should happen in each, even when the sample does not exercise it. Missing a rare case is usually worse than being slightly inexact on a common one.
3. **Parsimony.** Prefer the shortest rule consistent with the data. Long nested branches enumerating specific coordinates almost always overfit.
4. **No episode or step references.** "Episode N ended at step T" is not a rule you can use at deployment. Conditions must depend only on the arguments your function receives.
5. **One coherent hypothesis.** When several samples disagree, choose the single most general rule consistent with all of them - do not stack special cases for each one.

Pinductor — OUTPUT

Based on the environment description and analyzed observations, here is the inferred model of the dynamics:

****1. Dynamics & Hidden Variables****

- **Grid & Layout:** A fixed 10 $\times$ 10 grid. Boundary walls are at $x=0$, $x=9$, $y=0$, $y=9$. The interior $(1..8, 1..8)$ is mostly empty.
- **Lava Column:** A single column $x = 1$ ($1 < x < 9$) is filled with **lava**, except for exactly one **gap** at $y = g$. This gap allows the agent to pass.
- **Randomization:** The lava column index l and the gap row index g are randomized at the start of each episode.
- **Goal:** Located at $(8, 8)$. Stepping onto it yields a reward of +1 and ends the episode.
- **Transitions:** Moving forward moves the agent 1 step in the current direction. Turning changes direction. Hitting walls, boundaries, or lava blocks forward movement.
- **Observations:** A 3 $\times$ 3 field of view centered on the agent, rotated to face forward. The agent is always visible at 'image[1, 2]'.

****2. Implementation****

```

Curtis et al. — INPUT (transition_func call, full-state)

```

#define system
You are a robot exploring its environment.

Environment Description: 10x10 grid with boundary walls. A vertical wall of lava spans most of one
    column with exactly one gap to pass through. Agent starts at (1,1). Goal is at the bottom-right
    corner. The lava column position and gap position VARY between episodes.
Goal Description:

Your goal is to model the distribution of next states conditioned on actions and previous states.
You need to implement the python code to model the world, as seen in the provided experiences.
Please follow the template to implement the code.
The code needs to be directly runnable (state, action) and return a sample (next_state).

Below are a few samples from the environment distribution. These are only samples from a larger
distribution that you should model.

```

    Returns:
        new_state (MinigridState): the new state of the environment
    """
    raise NotImplementedError

```

Explain what you believe is the distribution of next states conditioned on actions and previous states in english.

Additionally, please implement code to model the logic of the world. Please implement the code following the template. Only output the definition for ' transition_func ' .

You must implement the ' transition_func ' function.

Create any helper function inside the scope of ' transition_func ' .

Do not create any helper function outside the scope of ' transition_func ' .

Do not output examples usage.

Do not create any new classes.

Do not rewrite existing classes.

Do not import any new modules from anywhere.

Do not overfit to the specific samples.

Put the ' transition_func ' function in a python code block.

Curtis et al. — OUTPUT

The environment follows a deterministic grid-world transition model. Given a state and an action, the next state is uniquely determined:

- **Turning (Actions 0 & 1)**:** Changes the agent's direction cyclically ('-1' or '+1' modulo 4) without altering position or the environment grid.
- **Forward Move (Action 2)**:** The agent attempts to move one cell in its current facing direction. The move succeeds only if the target cell is within grid boundaries and does not contain an impassable obstacle (walls or lava). If successful, 'agent_pos' updates; otherwise, the agent stays in place.
- **Other Actions (3-6)**:** Have no effect on the agent's pose or the grid in this specific setup, leaving the state unchanged.
- **Grid & Inventory**:** The 'grid' and 'carrying' fields remain static across these transitions. Lava acts as a hard barrier, matching the "wall of lava" description where only the gap allows passage.

```

'''python
def transition_func(state, action):
    """
    Args:
        state (MinigridState): the state of the environment
        action (int): action to be taken in state 'state'
    Returns:

```

```

        new_state (MinigridState): the new state of the environment
    """

I.2 Refinement iteration (UNLOCK for Pinductor online; LAVA iter-1 for Curtis et al.)

Pinductor — INPUT (post-episode-0 online refit, joint, particle-filter feedback)

```

#define system
You are a robot exploring its environment through partial observations.

ENVIRONMENT
-----
11x6 grid (two 6x6 rooms connected through a locked door at column 5) with boundary walls. A key is
placed in the accessible left room, and the goal is located behind the locked door in the right
room. Agent starts in the left room with random position and direction. The room layout is fixed,
while agent start position, key position, and goal position VARY between episodes.

GOAL
----

Your task is to improve the distribution of initial states, observations, transitions, and rewards
implemented in Python.

OBSERVED DATA
-----
Below are samples of actions and resulting observations from the real environment.
The true state is hidden - you only see observations (the agent's partial view).
Use these to verify your understanding of the world dynamics.

--- Episode 1 ---

'''

EVALUATION RESULTS
-----
Your code was evaluated against the observed data. Here are the results:

MODEL FIT
-----
Overall PF score: -18.86
(0 = perfect prediction, more negative = worse)

OBSERVATION EXPLANATION
-----
Best particle distance: 0.000
Median particle distance: 3.011
Distance variance: 3.067

Interpretation:
- Best particle distance measures whether ANY state explains the observation.
- Median distance measures how well the particle belief explains observations overall.
- Large gap between best and median indicates transition or inference problems.

PARTICLE FILTER HEALTH
-----
Mean effective sample size (ESS): 324.90
Minimum ESS during episode: 1.54
(Max possible ESS = number of particles + rejuvenation)

Interpretation:
- Low ESS indicates particle degeneracy (few particles explain observations).
- Persistent low ESS suggests transition model mismatch or insufficient particles.

PREDICTION ACCURACY BY CONTEXT (observation, action)
-----
Contexts where your model predicts poorly:
  observation=[[2, 2, 4], [1, 1, 12], [1, 1, 7]] + action=LEFT: avg_score=-2.1026 (n=1) [obs changes
  here]
  observation=[[2, 1, 1], [4, 1, 12], [2, 1, 1]] + action=LEFT: avg_score=-1.4617 (n=1) [obs changes
  here]
  observation=[[1, 2, 1], [1, 4, 12], [1, 2, 1]] + action=LEFT: avg_score=-1.4572 (n=1) [obs changes
  here]

Contexts marked [obs changes here] are steps where the agent's observation shifts between consecutive
time-steps (something entered or left the field of view, or the pose changed). Prediction errors
at these steps usually mean your transition_func mishandles the underlying state change - check
the rule that decides whether an action is blocked, succeeds, or alters the agent's pose.

MODEL UNCERTAINTY (your candidate models disagree on these cases):
-----
- When agent sees FOV=[[1,1,1] | [1,1,12] | [2,2,6]], action=2: models DISAGREE on 2/10 particles
  (agree on 8/10). (seen at step 11, agent took 1 instead)
- When agent sees FOV=[[2,2,2] | [1,1,12] | [1,1,1]], action=2: models DISAGREE on 1/10 particles
  (agree on 9/10). (seen at step 1, agent took 1 instead)
- When agent sees FOV=[[2,2,2] | [7,1,12] | [1,1,1]], action=2: models DISAGREE on 1/10 particles
  (agree on 9/10). (seen at step 2, agent took 2 instead)
- When agent sees FOV=[[2,2,2] | [2,7,12] | [2,1,1]], action=2: models DISAGREE on 1/10 particles
  (agree on 9/10). (seen at step 3, agent took 2 instead)
- When agent sees FOV=[[2,2,2] | [2,1,12] | [2,1,1]], action=2: models DISAGREE on 1/10 particles
  (agree on 9/10). (seen at step 4, agent took 3 instead)

```

These disagreements indicate uncertain transition rules. Think carefully about what should happen in each case. The majority vote is not always correct.

INSTRUCTIONS

1. First, analyze: for each reported error or disagreement above, explain in plain English what you think went wrong and why.
2. Then, fix: implement an improved version of the `initial_func`, `observation_func`, `transition_func`, `reward_func`, and `initial_func` functions. Focus on the specific cases where the evaluation found errors.

Rules:

- You must implement the `initial_func`, `observation_func`, `transition_func`, `reward_func`, and `initial_func` functions.
- Do not create new classes or import new modules.
- Do not overfit to specific indices - use general rules.
- Put the `initial_func`, `observation_func`, `transition_func`, `reward_func`, and `initial_func` functions in a python code block.

Generalization principles

Your goal is a **world model**: a compact, general description of how the environment behaves, not a lookup table of the samples you have seen.

1. **Rules over memorization.** Express conditions on semantic content, not on the literal arrays present in the samples.
2. **Cover the space, not the sample.** Enumerate every plausible case the environment can produce and decide what should happen in each, even when the sample does not exercise it.
3. **Parsimony.** Prefer the shortest rule consistent with the data. Long nested branches enumerating specific coordinates almost always overfit.
4. **No episode or step references.** Conditions must depend only on the arguments your function receives, not on which sample they came from.
5. **One coherent hypothesis.** When several samples disagree, choose the single most general rule consistent with all of them - do not stack special cases for each one.
6. **Keep what was already right.** When extending your previous code, do not drop a case that already worked. Add the new case alongside.

Pinductor — OUTPUT

Looking at the evaluation results, I can identify several critical issues:

1. **Initial state not properly cleaning old objects:** The `'initial_func'` copies `'empty_state.grid'` but never clears previous episode's key/goal/door positions before placing new ones, causing contamination.
2. **Wall structure at column 5 not enforced:** The locked door is placed at a random row in column 5, but the rest of column 5 must be filled with walls to form the partition.
3. **Agent position type inconsistency:** `'initial_func'` uses tuples while `'transition_func'` uses lists, which can cause subtle numpy indexing issues.
4. **Forward movement blocking logic incomplete:** The agent should not move into walls, closed doors, or locked doors, but the current allowed set doesn't explicitly account for all cases.
5. **The 'empty'/wall boundary assumption:** The code assumes boundary walls exist, but they need to be explicitly set in every initialization.

Here's the corrected implementation:

```
'''python
def initial_func(empty_state: MinigridState) -> MinigridState:
    """Samples a plausible initial state."""
    h = empty_state.grid.shape[1]
    w = empty_state.grid.shape[0]

    state = MinigridState(
        grid=np.full((w, h), ObjectTypes.wall, dtype=np.int8),
        agent_pos=(0, 0),
        agent_dir=0,
        carrying=None
    )

    # Clear interior (leave boundary walls)
    state.grid[1:w-1, 1:h-1] = ObjectTypes.empty

    # Place partition wall at column 5, rows 1 to h-2
    state.grid[5, 1:h-1] = ObjectTypes.wall

    # Random agent position in left room (columns 1-4)
    agent_x = random.randint(1, 4)
```

```

agent_y = random.randint(1, h - 2)
state.agent_pos = (agent_x, agent_y)
state.agent_dir = random.randint(0, 3)

# Place key in left room (not on agent)
while True:
    key_x = random.randint(1, 4)
    key_y = random.randint(1, h - 2)
    if (key_x, key_y) != state.agent_pos:
        break
state.grid[key_x, key_y] = ObjectTypes.key

# Place locked door in partition at column 5
door_y = random.randint(1, h - 2)
state.grid[5, door_y] = ObjectTypes.locked_door

# Place goal in right room (columns 6-9)
while True:
    goal_x = random.randint(6, 9)
    goal_y = random.randint(1, h - 2)
    if (goal_x, goal_y) != state.agent_pos:
        break
state.grid[goal_x, goal_y] = ObjectTypes.goal

# Terminate and reward when agent steps onto goal via forward action
if action == Actions.forward:
    ax, ay = next_state.agent_pos
    if 0 <= ax < next_state.width and 0 <= ay < next_state.height:
        if next_state.grid[ax, ay] == ObjectTypes.goal:
            reward = 1.0
            done = True

    return reward, done
'''

**Key fixes:**
1. **Proper grid initialization**: Uses 'np.full' with walls, then explicitly clears the interior and places the partition wall at column 5. This eliminates contamination from previous episodes.
2. **Explicit wall placement**: Column 5 is filled with walls at all interior rows, then one cell is replaced with the locked door.
3. **Consistent position types**: Uses 'list(state.agent_pos)' in transition to match tuple-to-list conversion, preventing numpy broadcasting issues.
4. **Bounds checking in reward**: Added explicit bounds validation before accessing the goal position in 'reward_func'.
5. **Clean object placement**: Used 'while True' loops with position checks to avoid placing objects on the agent.

```

Curtis et al. — INPUT (transition_func REX iter 1, identical template to online hook)

```

#define system
You are a robot exploring its environment.

10x10 grid with boundary walls. A vertical wall of lava spans most of one column with exactly one gap to pass through. Agent starts at (1,1). Goal is at the bottom-right corner. The lava column position and gap position VARY between episodes.

Your goal is to model the distribution of next states conditioned on actions and previous states of the world in python.

You have tried it before and came up with one partially correct solution, but it is not perfect.

The observed distribution disagrees with the generated model in several cases.
You need to improve your code to come closer to the true distribution.

Environment Description: 10x10 grid with boundary walls. A vertical wall of lava spans most of one column with exactly one gap to pass through. Agent starts at (1,1). Goal is at the bottom-right corner. The lava column position and gap position VARY between episodes.
Goal Description:

Here is a solution you came up with before.

Explain what you believe is the distribution of next states conditioned on actions and previous states in english, then improve your code to better model the true distribution.

Please implement the code for the following the template.
You must implement the ' transition_func ' function.

The code needs to be directly runnable (state, action) and return a sample (next_state).

Do not output examples.
Do not create any new classes.
Do not rewrite existing classes.
Do not import any new modules from anywhere.
Do not list out specific indices that overfit to the examples, but include ranges.
Put the ' transition_func ' function in a python code block.

Curtis et al. — OUTPUT

Based on the provided examples, the key discrepancy is that your current model treats lava ('ObjectTypes.lava') as an impassable obstacle. However, the real-world transitions clearly show the agent successfully moving forward into cells containing lava. This indicates that in this specific environment, lava cells are **traversable** and only boundary/structural walls ('ObjectTypes.wall') block movement.

To align your model with the true distribution, you should remove the lava check from the walkability condition.

Here is the improved 'transition_func':

```
'''python
def transition_func(state, action):
```

```

"""
Args:
    state (MinigridState): the state of the environment
    action (int): action to be taken in state 'state'
Returns:
    new_state (MinigridState): the new state of the environment
"""
def _is_cell_walkable(grid, x, y):
    # Check boundaries
    if x < 0 or x >= grid.shape[1] or y < 0 or y >= grid.shape[0]:
        return False
    # Check against impassable terrain (only walls are impassable here)
    cell = grid[y][x]
    return cell != ObjectTypes.wall

new_pos = state.agent_pos
new_dir = state.agent_dir
new_carrying = state.carrying

if action == Actions.left:
    new_dir = (state.agent_dir - 1) % 4
elif action == Actions.right:
    new_dir = (state.agent_dir + 1) % 4
elif action == Actions.forward:
    dx, dy = DIR_TO_VEC[state.agent_dir]
    next_x = new_pos[0] + dx
    next_y = new_pos[1] + dy

    if _is_cell_walkable(state.grid, next_x, next_y):
        new_pos = (next_x, next_y)

# Actions 3 through 6 do not modify pose or inventory in this environment configuration

return MinigridState(
    grid=state.grid,
    agent_pos=new_pos,
    agent_dir=new_dir,
    carrying=new_carrying
)
'''

```

NeurIPS Paper Checklist

1. Claims

Question: Do the main claims made in the abstract and introduction accurately reflect the paper’s contributions and scope?

Answer: [Yes]

Justification: The abstract and introduction state three contributions — inducing POMDP models without hidden-state access, a belief-based kernel likelihood objective, and empirical characterization of the method’s dependencies — each of which is directly evaluated in Section 5 (main results, sample efficiency, LLM ablation, prompt and semantic ablations).

Guidelines:

- The answer [N/A] means that the abstract and introduction do not include the claims made in the paper.
- The abstract and/or introduction should clearly state the claims made, including the contributions made in the paper and important assumptions and limitations. A [No] or [N/A] answer to this question will not be perceived well by the reviewers.
- The claims made should match theoretical and experimental results, and reflect how much the results can be expected to generalize to other settings.
- It is fine to include aspirational goals as motivation as long as it is clear that these goals are not attained by the paper.

2. Limitations

Question: Does the paper discuss the limitations of the work performed by the authors?

Answer: [Yes]

Justification: Limitations are discussed in the Discussion section, covering the hand-designed observation distance function, manually collected offline trajectories, the absence of cross-environment generalization evaluation, and the absence of evaluations outside MiniGrid.

Guidelines:

- The answer [N/A] means that the paper has no limitation while the answer [No] means that the paper has limitations, but those are not discussed in the paper.
- The authors are encouraged to create a separate “Limitations” section in their paper.
- The paper should point out any strong assumptions and how robust the results are to violations of these assumptions (e.g., independence assumptions, noiseless settings, model well-specification, asymptotic approximations only holding locally). The authors should reflect on how these assumptions might be violated in practice and what the implications would be.
- The authors should reflect on the scope of the claims made, e.g., if the approach was only tested on a few datasets or with a few runs. In general, empirical results often depend on implicit assumptions, which should be articulated.
- The authors should reflect on the factors that influence the performance of the approach. For example, a facial recognition algorithm may perform poorly when image resolution is low or images are taken in low lighting. Or a speech-to-text system might not be used reliably to provide closed captions for online lectures because it fails to handle technical jargon.
- The authors should discuss the computational efficiency of the proposed algorithms and how they scale with dataset size.
- If applicable, the authors should discuss possible limitations of their approach to address problems of privacy and fairness.
- While the authors might fear that complete honesty about limitations might be used by reviewers as grounds for rejection, a worse outcome might be that reviewers discover limitations that aren’t acknowledged in the paper. The authors should use their best judgment and recognize that individual actions in favor of transparency play an important role in developing norms that preserve the integrity of the community. Reviewers will be specifically instructed to not penalize honesty concerning limitations.

3. Theory assumptions and proofs

Question: For each theoretical result, does the paper provide the full set of assumptions and a complete (and correct) proof?

Answer: [N/A]

Justification: The paper presents no theoretical results.

Guidelines:

- The answer [N/A] means that the paper does not include theoretical results.
- All the theorems, formulas, and proofs in the paper should be numbered and cross-referenced.
- All assumptions should be clearly stated or referenced in the statement of any theorems.
- The proofs can either appear in the main paper or the supplemental material, but if they appear in the supplemental material, the authors are encouraged to provide a short proof sketch to provide intuition.
- Inversely, any informal proof provided in the core of the paper should be complemented by formal proofs provided in appendix or supplemental material.
- Theorems and Lemmas that the proof relies upon should be properly referenced.

4. Experimental result reproducibility

Question: Does the paper fully disclose all the information needed to reproduce the main experimental results of the paper to the extent that it affects the main claims and/or conclusions of the paper (regardless of whether the code and data are provided or not)?

Answer: [Yes]

Justification: The full algorithm is given in Algorithm 1; the objective and observation distance function are defined in Section 4; environments, baselines, hyperparameters, seeding protocol, and evaluation procedure are described in Section 5.1; remaining hyperparameter values are provided in Appendix A.4. Code and offline trajectory data are released as supplementary material.

Guidelines:

- The answer [N/A] means that the paper does not include experiments.
- If the paper includes experiments, a [No] answer to this question will not be perceived well by the reviewers: Making the paper reproducible is important, regardless of whether the code and data are provided or not.
- If the contribution is a dataset and/or model, the authors should describe the steps taken to make their results reproducible or verifiable.
- Depending on the contribution, reproducibility can be accomplished in various ways. For example, if the contribution is a novel architecture, describing the architecture fully might suffice, or if the contribution is a specific model and empirical evaluation, it may be necessary to either make it possible for others to replicate the model with the same dataset, or provide access to the model. In general, releasing code and data is often one good way to accomplish this, but reproducibility can also be provided via detailed instructions for how to replicate the results, access to a hosted model (e.g., in the case of a large language model), releasing of a model checkpoint, or other means that are appropriate to the research performed.
- While NeurIPS does not require releasing code, the conference does require all submissions to provide some reasonable avenue for reproducibility, which may depend on the nature of the contribution. For example
 - (a) If the contribution is primarily a new algorithm, the paper should make it clear how to reproduce that algorithm.
 - (b) If the contribution is primarily a new model architecture, the paper should describe the architecture clearly and fully.
 - (c) If the contribution is a new model (e.g., a large language model), then there should either be a way to access this model for reproducing the results or a way to reproduce the model (e.g., with an open-source dataset or instructions for how to construct the dataset).

- (d) We recognize that reproducibility may be tricky in some cases, in which case authors are welcome to describe the particular way they provide for reproducibility. In the case of closed-source models, it may be that access to the model is limited in some way (e.g., to registered users), but it should be possible for other researchers to have some path to reproducing or verifying the results.

5. Open access to data and code

Question: Does the paper provide open access to the data and code, with sufficient instructions to faithfully reproduce the main experimental results, as described in supplemental material?

Answer: [Yes]

Justification: We release the code and offline trajectory datasets at submission time in a zip file. A GitHub repository containing all elements for reproducing the main experiments will be made available upon acceptance.

Guidelines:

- The answer [N/A] means that paper does not include experiments requiring code.
- Please see the NeurIPS code and data submission guidelines (<https://neurips.cc/public/guides/CodeSubmissionPolicy>) for more details.
- While we encourage the release of code and data, we understand that this might not be possible, so [No] is an acceptable answer. Papers cannot be rejected simply for not including code, unless this is central to the contribution (e.g., for a new open-source benchmark).
- The instructions should contain the exact command and environment needed to run to reproduce the results. See the NeurIPS code and data submission guidelines (<https://neurips.cc/public/guides/CodeSubmissionPolicy>) for more details.
- The authors should provide instructions on data access and preparation, including how to access the raw data, preprocessed data, intermediate data, and generated data, etc.
- The authors should provide scripts to reproduce all experimental results for the new proposed method and baselines. If only a subset of experiments are reproducible, they should state which ones are omitted from the script and why.
- At submission time, to preserve anonymity, the authors should release anonymized versions (if applicable).
- Providing as much information as possible in supplemental material (appended to the paper) is recommended, but including URLs to data and code is permitted.

6. Experimental setting/details

Question: Does the paper specify all the training and test details (e.g., data splits, hyperparameters, how they were chosen, type of optimizer) necessary to understand the results?

Answer: [Yes]

Justification: Hyperparameters, seeding protocol, and evaluation procedure are described in Section 5.1; remaining hyperparameter values are provided in Appendix A.4. Pinductor is the optimizer itself and is explained in detail.

Guidelines:

- The answer [N/A] means that the paper does not include experiments.
- The experimental setting should be presented in the core of the paper to a level of detail that is necessary to appreciate the results and make sense of them.
- The full details can be provided either with the code, in appendix, or as supplemental material.

7. Experiment statistical significance

Question: Does the paper report error bars suitably and correctly defined or other appropriate information about the statistical significance of the experiments?

Answer: [Yes]

Justification: Error bars / shaded regions are 95% CI computed over the 10 independent run seeds, each summarised by its mean over the 3 evaluation episodes. The source of variability (run seed) and the evaluation protocol (10 seeds $\times$ 3 episodes) are described in Appendix H.2.

Guidelines:

- The answer [N/A] means that the paper does not include experiments.
- The authors should answer [Yes] if the results are accompanied by error bars, confidence intervals, or statistical significance tests, at least for the experiments that support the main claims of the paper.
- The factors of variability that the error bars are capturing should be clearly stated (for example, train/test split, initialization, random drawing of some parameter, or overall run with given experimental conditions).
- The method for calculating the error bars should be explained (closed form formula, call to a library function, bootstrap, etc.)
- The assumptions made should be given (e.g., Normally distributed errors).
- It should be clear whether the error bar is the standard deviation or the standard error of the mean.
- It is OK to report 1-sigma error bars, but one should state it. The authors should preferably report a 2-sigma error bar than state that they have a 96% CI, if the hypothesis of Normality of errors is not verified.
- For asymmetric distributions, the authors should be careful not to show in tables or figures symmetric error bars that would yield results that are out of range (e.g., negative error rates).
- If error bars are reported in tables or plots, the authors should explain in the text how they were calculated and reference the corresponding figures or tables in the text.

8. Experiments compute resources

Question: For each experiment, does the paper provide sufficient information on the computer resources (type of compute workers, memory, time of execution) needed to reproduce the experiments?

Answer: [Yes]

Justification: Compute resource details (hardware, wall-clock time per run, total compute, and LLM API call counts) are described in Appendix H.1.

Guidelines:

- The answer [N/A] means that the paper does not include experiments.
- The paper should indicate the type of compute workers CPU or GPU, internal cluster, or cloud provider, including relevant memory and storage.
- The paper should provide the amount of compute required for each of the individual experimental runs as well as estimate the total compute.
- The paper should disclose whether the full research project required more compute than the experiments reported in the paper (e.g., preliminary or failed experiments that didn't make it into the paper).

9. Code of ethics

Question: Does the research conducted in the paper conform, in every respect, with the NeurIPS Code of Ethics <https://neurips.cc/public/EthicsGuidelines>?

Answer: [Yes]

Justification: The research conforms with the NeurIPS Code of Ethics.

Guidelines:

- The answer [N/A] means that the authors have not reviewed the NeurIPS Code of Ethics.
- If the authors answer [No], they should explain the special circumstances that require a deviation from the Code of Ethics.

- The authors should make sure to preserve anonymity (e.g., if there is a special consideration due to laws or regulations in their jurisdiction).

10. **Broader impacts**

Question: Does the paper discuss both potential positive societal impacts and negative societal impacts of the work performed?

Answer: [N/A]

Justification: This paper presents foundational research on world-model learning from partial observations. There is no direct path to specific negative societal applications.

Guidelines:

- The answer [N/A] means that there is no societal impact of the work performed.
- If the authors answer [N/A] or [No], they should explain why their work has no societal impact or why the paper does not address societal impact.
- Examples of negative societal impacts include potential malicious or unintended uses (e.g., disinformation, generating fake profiles, surveillance), fairness considerations (e.g., deployment of technologies that could make decisions that unfairly impact specific groups), privacy considerations, and security considerations.
- The conference expects that many papers will be foundational research and not tied to particular applications, let alone deployments. However, if there is a direct path to any negative applications, the authors should point it out. For example, it is legitimate to point out that an improvement in the quality of generative models could be used to generate Deepfakes for disinformation. On the other hand, it is not needed to point out that a generic algorithm for optimizing neural networks could enable people to train models that generate Deepfakes faster.
- The authors should consider possible harms that could arise when the technology is being used as intended and functioning correctly, harms that could arise when the technology is being used as intended but gives incorrect results, and harms following from (intentional or unintentional) misuse of the technology.
- If there are negative societal impacts, the authors could also discuss possible mitigation strategies (e.g., gated release of models, providing defenses in addition to attacks, mechanisms for monitoring misuse, mechanisms to monitor how a system learns from feedback over time, improving the efficiency and accessibility of ML).

11. **Safeguards**

Question: Does the paper describe safeguards that have been put in place for responsible release of data or models that have a high risk for misuse (e.g., pre-trained language models, image generators, or scraped datasets)?

Answer: [N/A]

Justification: The paper does not release pretrained language models, image generators, or scraped datasets. The released code is a research implementation with no identified misuse risk.

Guidelines:

- The answer [N/A] means that the paper poses no such risks.
- Released models that have a high risk for misuse or dual-use should be released with necessary safeguards to allow for controlled use of the model, for example by requiring that users adhere to usage guidelines or restrictions to access the model or implementing safety filters.
- Datasets that have been scraped from the Internet could pose safety risks. The authors should describe how they avoided releasing unsafe images.
- We recognize that providing effective safeguards is challenging, and many papers do not require this, but we encourage authors to take this into account and make a best faith effort.

12. **Licenses for existing assets**

Question: Are the creators or original owners of assets (e.g., code, data, models), used in the paper, properly credited and are the license and terms of use explicitly mentioned and properly respected?

Answer: [\[Yes\]](#)

Justification: All existing assets are properly credited and licenses mentioned in Appendix [H.3](#)

Guidelines:

- The answer [\[N/A\]](#) means that the paper does not use existing assets.
- The authors should cite the original paper that produced the code package or dataset.
- The authors should state which version of the asset is used and, if possible, include a URL.
- The name of the license (e.g., CC-BY 4.0) should be included for each asset.
- For scraped data from a particular source (e.g., website), the copyright and terms of service of that source should be provided.
- If assets are released, the license, copyright information, and terms of use in the package should be provided. For popular datasets, paperswithcode.com/datasets has curated licenses for some datasets. Their licensing guide can help determine the license of a dataset.
- For existing datasets that are re-packaged, both the original license and the license of the derived asset (if it has changed) should be provided.
- If this information is not available online, the authors are encouraged to reach out to the asset's creators.

13. New assets

Question: Are new assets introduced in the paper well documented and is the documentation provided alongside the assets?

Answer: [\[N/A\]](#)

Justification: The paper does not introduce a new dataset, benchmark, or standalone asset as a primary contribution. The environments are based on MiniGrid, and all third-party assets are credited in Appendix [H.3](#). Code and trajectory data used for the experiments are made available.

Guidelines:

- The answer [\[N/A\]](#) means that the paper does not release new assets.
- Researchers should communicate the details of the dataset/code/model as part of their submissions via structured templates. This includes details about training, license, limitations, etc.
- The paper should discuss whether and how consent was obtained from people whose asset is used.
- At submission time, remember to anonymize your assets (if applicable). You can either create an anonymized URL or include an anonymized zip file.

14. Crowdsourcing and research with human subjects

Question: For crowdsourcing experiments and research with human subjects, does the paper include the full text of instructions given to participants and screenshots, if applicable, as well as details about compensation (if any)?

Answer: [\[N/A\]](#)

Justification: The paper does not involve crowdsourcing or research with human subjects.

Guidelines:

- The answer [\[N/A\]](#) means that the paper does not involve crowdsourcing nor research with human subjects.
- Including this information in the supplemental material is fine, but if the main contribution of the paper involves human subjects, then as much detail as possible should be included in the main paper.
- According to the NeurIPS Code of Ethics, workers involved in data collection, curation, or other labor should be paid at least the minimum wage in the country of the data collector.

15. Institutional review board (IRB) approvals or equivalent for research with human subjects

Question: Does the paper describe potential risks incurred by study participants, whether such risks were disclosed to the subjects, and whether Institutional Review Board (IRB) approvals (or an equivalent approval/review based on the requirements of your country or institution) were obtained?

Answer: [N/A]

Justification: The paper does not involve crowdsourcing or research with human subjects.

Guidelines:

- The answer [N/A] means that the paper does not involve crowdsourcing nor research with human subjects.
- Depending on the country in which research is conducted, IRB approval (or equivalent) may be required for any human subjects research. If you obtained IRB approval, you should clearly state this in the paper.
- We recognize that the procedures for this may vary significantly between institutions and locations, and we expect authors to adhere to the NeurIPS Code of Ethics and the guidelines for their institution.
- For initial submissions, do not include any information that would break anonymity (if applicable), such as the institution conducting the review.

16. Declaration of LLM usage

Question: Does the paper describe the usage of LLMs if it is an important, original, or non-standard component of the core methods in this research? Note that if the LLM is used only for writing, editing, or formatting purposes and does *not* impact the core methodology, scientific rigor, or originality of the research, declaration is not required.

Answer: [Yes]

Justification: LLMs are a core and original component of PinDuctor: they propose and iteratively repair executable POMDP programs based on observation-action trajectories and belief-based feedback. This is described throughout Section 4 and evaluated in Section 5.

Guidelines:

- The answer [N/A] means that the core method development in this research does not involve LLMs as any important, original, or non-standard components.
- Please refer to our LLM policy in the NeurIPS handbook for what should or should not be described.
